ABSTRACT

Background: Cell-therapy has been promoted among the therapeutic arsenal that can aid in bone formation and remodeling, in early stages of osteonecrosis of the femoral head (ONFH). The purpose of this systematic review was to assess the evidence supporting the (1) clinical efficacy; (2) structural modifying effect, as evaluated radiographically; (3) revision rates; and (4) safety of cell-therapy for the treatment of ONFH.

Methods: A systematic review was performed including studies with a level-of-evidence of III or higher. A total of 1483 articles were screened. Eleven studies met the criteria for inclusion in this review (level-of-evidence: 6 level-I, 1 level-II, and 4 level-III), including 683 cases of ONFH.

Results: All 10 studies that reported patient-reported outcomes showed improved outcomes in the cell-therapy groups compared with the control group. Overall, 24.5% (93/380 hips) that received cell-therapy showed radiographic progression compared with 40% (98/245 hips) in the control group. Nine of 10 studies that reported failure rates showed a lower total hip arthroplasty conversion rate in the cell-therapy group 16% (62/380 hips) compared with the control group 21% (52/252 hips). There was a low complication rate (<3%) with no major adverse effects.

Conclusion: Cell-therapies for the treatment of ONFH have been reported to be safe and suggest improved clinical outcomes with lower disease progression rate. However, there was substantial heterogeneity in the included studies, and in the cell-based therapies used. Specific clinical indications and cell-therapy standardization are required because studies varied widely with respect to cell sourcing, cell characterization, adjuvant therapies, and assessment of outcomes.

Osteonecrosis of the femoral head (ONFH) accounts for approximately 8%-12% of all total hip arthroplasty (THA) cases in the United States [1]. It is characterized by compromised subchondral microcirculation, necrosis of the bone, and microfracture

One or more of the authors of this paper have disclosed potential or pertinent conflicts of interest, which may include receipt of payment, either direct or indirect, institutional support, or association with an entity in the biomedical field which may be perceived to have potential conflict of interest with this work. accumulation without sustained remodeling [2,3]. Because ONFH most frequently occurs in young patients, and progression to symptoms or collapse occurs in approximate 60% of asymptomatic patients, [3,4] joint preserving techniques should be considered in early precollapse stages, to avoid or delay the cost and risk of THA, especially when patients are caught in early (precollapse) stages [5].

Core decompression (CD) is a surgical technique for joint preservation in early ONFH, typically performed by drilling to remove a cylindrical core through the femoral neck deep into the osteonecrotic lesion [1,6]. This is believed to reduce the pressure in the femoral head and open an unobstructed path through which potential

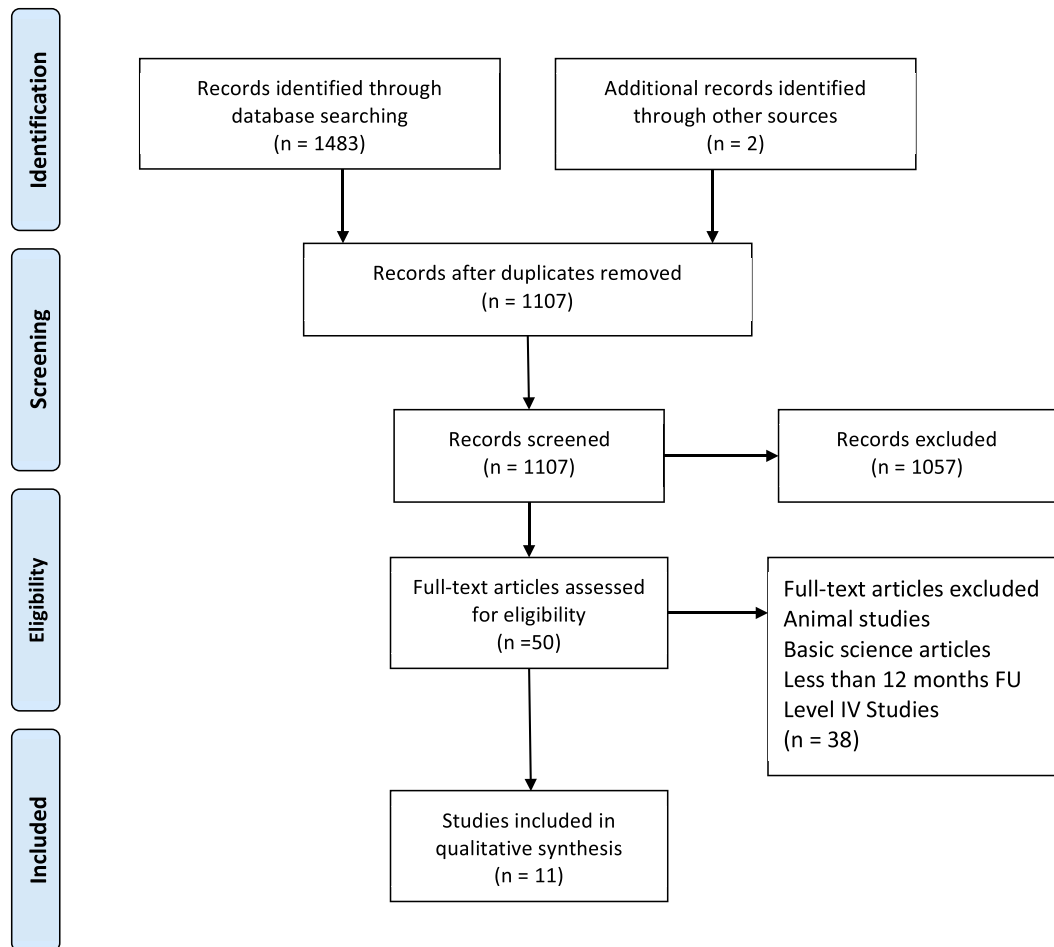

Fig. 1. Flow diagram presenting the systematic review process used in this study.

revascularization can occur with restoration of bone formation and remodeling. However, long-term results on this procedure can be unpredictable [7], and its efficacy remains an area of controversy [6].

Currently, there is no consensus regarding the treatment of early stages of ONFH [2]. Although a variety of treatments, ranging from nonoperative (eg, bisphosphonates) to operative (CD, bone grafting, vascularized fibular grafting, rotational osteotomy, etc.) have been proposed, none of these have been proven to be clearly superior so that widespread adoption has occurred. To date, THA is the most frequent intervention for postcollapse treatment, and CD is commonly performed for symptomatic, precollapse cases [8]. Adjunctive techniques have been described in an attempt to improve CD outcomes, and specifically cell-based therapies are being explored to restore the local cell population and to establish effective bone remodeling [9,10]. The purpose of the present study was to provide a systematic review of the current literature on the use of cell-based therapies for the treatment of ONFH. Our specific aims were to examine the evidence supporting their (1) clinical efficacy; (2) structural modifying effect, as evaluated radiographically; (3) revision rates; and (4) safety.

Materials and Methods

Article Identification and Selection

This study was conducted in accordance with the 2009 Preferred Reporting Items for Systematic Review and Meta-Analysis statement

[11]. Reports were identified by using an electronic search of keyword terms and combinations. A systematic review of the literature regarding the cell therapy treatment of ONFH in human patients was performed using the Cochrane Database of Systematic Reviews, the Cochrane Central Register of Controlled Trials, PubMed (1990-2016), and Medline (1990-2016). The queries were performed in October of 2016.

Four different searching criteria were used, using the search terms: cell-therapy, stem-cells, hip, osteonecrosis, and avascular necrosis:

Search 1

Studies were included in this systematic review if the reports contained clinical and/or radiological outcomes for cell therapy in the treatment of ONFH with a minimum follow-up of 12 months, and had a level of evidence of I, II, or III. All included articles were presented in the English language, and were performed on human subjects. Exclusion criteria were as follows: cadaveric studies, animal studies, basic science articles, editorials, surveys, special topics, letters to the editor, and personal correspondence.

Two authors performed the initial search (N. S. P., J. C.), and three investigators (N. S. P., C. P. G., J. C.) independently reviewed the abstracts from all identified articles and inclusion and exclusion criteria were applied based on the information presented therein. If one or more authors selected an article, it progressed to the following phase. Full-text articles were obtained to allow further assessment of inclusion and exclusion criteria, as needed. In addition, all references from the included studies were reviewed and reconciled to verify that no relevant articles were missing from the systematic review.

Level-of-evidence was assigned using classifications specified by Wright et al [12]. Data were recorded into a custom information extraction table [13].

Study Selection

Our initial systematic literature review yielded 1483 individual studies, of which 12 met the inclusion criteria and were

identified and included for analysis (Fig. 1). One study was excluded after communication with the authors to avoid patient duplication [14]. After review of the 11 remaining reports according to the level of evidence, 6 were level I, 1 was level II, and 4 were level III.

Patient Demographics

The 11 studies included 528 ONFH patients, as summarized in Table 1. Of the 683 hips, 416 hips received a cell therapy procedure for the treatment of ONFH and 155 were bilateral. Mean patient age was 37 years (range 27–49 years). The classification systems used were: Association Research Circulation Osseous classification [26,27]: 47 (grade I); 288 (grade II); and 50 (grade III) [14,15,17,19–21]. Ficat classification [28]: 7 (grade I); 134 (grade II); and 67 (grade III) [18,22]. Japanese Orthopaedic Association Staging: 2 (grade I), 25 (grade II), 3 grade IIIA and Mitchell staging system: 13 (grade A); 13 (grade B); 19 (grade C); and 1 (grade D) (5 patients were not classified according to the MRI Mitchell's classification because of hardware presence) [16]. From this data, it can be calculated that 81% of the studied hips were Ficat stages 1–2. Mean follow-up was 37 months (range 24–60 months).

Clinical Efficacy—Patient-Reported Outcome Measures

Ten of the 11 studies [15–25] analyzed the outcome of treatment in the cell therapy and control treatment groups using patient-reported outcomes (PROs; Tables 2 and 3). Three studies reported pretreatment and follow-up status using Western Ontario and McMaster Universities Arthritis Index (WOMAC) score [18,20,21]; and 6 studies reported pain using a visual analog scale (VAS) [14,18,20,21,23,25]. Six studies reported Harris Hip Score (HHS) outcomes [15–17,23,25]; however, one study did not include standard deviations [15]. Two studies [18,21] reported baseline and follow-up status using a Lequesne index. One study reported clinical outcome with the System of Merle d'Aubigne and Postel [24].

Structural Modifying Effect—Structural Assessment With Images

All 11 studies performed imaging structural assessments. Seven studies [15,16,19–21,24,25] did structural assessments with magnetic resonance imaging (MRI) (Tables 2 and 4), and 4 studies assessed disease progression through x-ray evaluation only [17,18,22,23,29]. Two hundred sixty-eight hips in 6 studies [15,16,18,20,23,25] were followed up for 24 months; 286 hips in 3 studies [19,21,22] were followed up for 60 months, 89 hips in one study [17] were followed up for 36 months, and 39 hips in one study were followed up for 18 months [24].

Revision Rates—Conversion to THA

Ten of the 11 studies reported failure rates based on conversion to THA [15,17–25].

Safety—Complications

Complications were reported in all 11 studies, although one of them did not provide details, and was excluded for the analysis [22].

Results

Overall cell therapies showed improved clinical outcome, decreased radiographic progression and decreased revision rate (Table 2).

Clinical Efficacy—Patient-Reported Outcome Measures

All 10 studies that reported PROs showed improved outcomes in the cell therapy groups (278 hips) compared with control groups (254 hips) (Table 3). The 5 studies that reported pain according to VAS demonstrated substantial improvement in cell therapy groups (91 hips) compared with control groups (90 hips) [2,16,19,24,30]. Two of these 5 studies reported similar favorable findings with WOMAC score evaluations (39 hips treated with cell therapy vs 38 hips treated with control group) [16,24], although one study [21] did not find differences between the cell therapy (13 hips) and the control group (11 hips). Nonetheless, this later study included the Lequesne index and reported significant difference in favor of cell therapy group (13 hips), compared with control group (11 hips) [21].

All 6 studies that provided a HHS score assessment showed improvement in both cell therapies (188 hips) and control groups (196 hips). Nevertheless, the improvement was greater among the cell therapy groups among the 6 studies [15–17,19,23,25].

Structural Modifying Effect—Structural Assessment With Images

Nine studies demonstrated a reduced progression, no progression, or even regression of ONFH lesions with the use of cell therapies (221 hips) compared with control groups (252 hips) [15–21,24,25]. In contrast, 2 studies [16,22] found no significant differences by MRI with the use of cell therapy (154 cell therapy cases vs 56 controls). Overall, 24.5% (93/380 hips) that received cell therapy showed radiographic progression compared with 40% (98/245 hips) in the control group (Table 4).

Revision Rate—Conversion to THA

Nine of 10 studies that reported revision rates showed a lower THA conversion rate in the cell therapy group 16% (62/380 hips) compared with the control group 21% (52/252 hips); however, the

CD, core decompression; N/A, not available; ONFH, osteonecrosis of the femoral head; THA, total hip arthroplasty.

difference was not significant in all studies: 0/10 to 3/30 (10%) [15]; 3/48 (6%) to 9/41 (22%) ($P = .031$) [17]; 2/25 (9%) to 4/24 (22%) [18]; 0/53 to 5/51 (11%) ($P < .05$) [19]; 2/13 (15%) to 3/11 (27%) ($P = .008$) [21]; 4/28 (14%) to 5/27 (19%) [23]; 1/30 (3%) to 3/9 (33%) [24]; 0/14 to 3/14 (21%) [20] and 4/11 (36%) to 6/14 (43%) ($P > .05$) [25] (see Table 5). Only one study had a higher THA conversion rate in the cell therapy group: 47/128 (37%) to 11/31 (35%) ($P < .8527$) [22], although this difference was not statistically significant.

Safety—Complications

From the 10 included studies (524 hips) that provided data on complications, there were a total of 15/524 (2.8%) reported complications (Table 5). For these minor complications, 6 complications appeared in the control group (6 adverse events/246 hips: 2.4%), and 8 complications in the cell therapy group (8 adverse/278 hips: 2.9%). There were no major adverse effects reported. The most common complaint was pain in association with a hematoma at the site of the CD and pain at the bone marrow aspiration site. Two patients had an infection [18,21]. One of the patients presented with a positive bacteriological culture of the bone marrow (coagulase negative staphylococci) and was treated with antibiotics, but had no clinical symptoms of sepsis [21]. The other patient was in a control group and experienced a postoperative infection that was successfully treated with antibiotics [17]. We did not find significant difference between cell therapy groups and control groups in terms of complications, and there were no reported events related to the cell therapy, no constitutional symptoms reported.

Discussion

The most important findings of this study were that the utilization of cell therapies in patients with early stages of ONFH when compared with their control groups showed overall: (1) favorable

results based on PROs; (2) a lower disease progression rate; (3) a lower failure rate; and (4) safety in the use of cell-based therapies with rare and minor complications.

Our systematic review had several limitations. First, there was a wide variation in the cell-based therapies used, specifically regarding the choice of cells, method of cell processing, cell characterization, quantitative and qualitative assessment of the cells used, surgical methods of cell delivery, the attributes of patient cohorts, and the outcome measures used. As a result, generalizable conclusions regarding the magnitude of treatment effect and the relative efficacy between the treatment strategies that have been evaluated must be made with caution. Second, the selection for success or failure was determined mainly by the end point of patient undergoing a THA, which may not be the most accurate measure. Third, although 81% of the studied hips were classified as Ficat stage I and stage II, we could not consistently analyze and correlate the size of lesion with progression, because it was infrequently reported. Fourth, the results presented in this study have a mean follow-up of 37 months (range 24–60 months), which could underestimate the progression and failure rate of these therapies. Despite these variations and limitations noted, these studies demonstrated generally beneficial effects of the cell-based therapies that warrant further investigation.

In each study, improvements in one or more PRO were reported for cell therapy groups when compared with non-cell therapy groups was found [15–25]. In our assessment, cell therapy with CD treatment showed improvement in modified Harris Hip Score, VAS, and WOMAC scores when compared with CD alone. Our findings are supported by other preclinical and clinical reviews on the use of cell therapy for the treatment of ONFH [29,31]. After pain and function, conversion to THA can be considered to be the next most important outcome. Eight of 9 studies [15,17–19,21,23–25] reporting on THA conversion reported lower rates in the cell therapy treatment groups. These reports should be considered positively and

may be promising. However, it must also be recognized that the decision to offer THA and the decision to accept THA are subjective decisions that are not immune from bias without double blind study design. Conversely structural modifying effect measured both by MRI and x-ray showed that cell-based therapies decreased the progression rate, with a more significant effect among earlier stages of ONFH.

The only study that did not encounter positive results in any aspect analyzed was Lim et al [22]. However, looking at the data, it appears that the cell group had a number of factors that could have introduced bias and predisposed to worse results: (1) steroid was the cause of ONFH in 56% of cases in the cell therapy group, whereas in the control group, it was 29% and (2) underlying disease in the cell therapy group comprised between leukemia, aplastic anemia, and kidney transplantation a 47%, whereas in the control group, it was 19%. These differences might have introduced bias because these causes are known to have worst result not only in hip preservation procedures but also in THA [1,2,4,6,30].

Based on the current literature, the use of cell therapies has been reported to be safe in multiple orthopedic settings [32–36]. In this study, the rate of complications was low, and we did not find any difference between the cell therapy group and control group. All complications reported were related to donor site morbidity, from the harvest site and there were no reports of complications attributed to the delivery of cells or follow-up.

At early stages of ONFH, hip preservation techniques are often preferred, specifically in younger patients [2,8,37–39]. The rationale for the use of a cell therapy approach is that regions of osteonecrosis can only be repaired by bone regeneration and remodeling through the action of bone forming osteogenic progenitors. As regenerative medicine and the application of cell therapies become available, a better understanding of these treatments will be required. Among the pool of “cell-based therapies”, more diversity was present, and stem and progenitor cell population varied among (1) sources; (2) patients; and (3) processing methods. Cell types available to be used may include (1) autologous or allogenic cells; (2) adult, embryonic, or induced pluripotential stem cells; and (3) native (tissue resident) stem and progenitor cells or cultured expanded cells (eg, mesenchymal stromal cells) [40–52]. The analysis and description of these heterogeneous cell therapy options are beyond the scope of this article.

Conclusion

Cell therapies in patients with early stages of ONFH suggest (1) improved clinical outcomes; (2) decreased radiographic progression of disease; (3) decreased revision rate; and (4) a low complication rate. There was a high heterogeneity in cell therapies used and the outcome measures selected. Cell therapies offer a promising future; nevertheless, its propagation and acceptance will demand the implementation of standardization to allow reproducibility. Additional blinded randomized control trials and clinical effectiveness trials with rigorous standards are needed to establish the efficacy of these therapies for the treatment of ONFH.
